Abstract

Context: Whether physical activity attenuates the association of total daily sitting time with cardiovascular disease (CVD) and diabetes incidence is unclear. This systematic review and meta-analysis examined the association of total daily sitting time with CVD and diabetes with and without adjustment for physical activity. Evidence Acquisition: PubMed, Web of Science, BASE, MEDLINE, Academic Search Elite and ScienceDirect were searched for prospective studies published between 1st January 1989 and 15th February 2019 examining the association of total daily sitting time with CVD or diabetes outcomes. Data extraction and study quality assessments were conducted by two independent reviewers. Pooled Hazard Ratios (HRs) were calculated using a fixed-effects model. The quality assessment and meta-analytic procedures were completed in 2018. Evidence Synthesis: Nine studies with 448,285 participants were included. Higher total daily sitting time was associated with a significantly increased risk of CVD (HR 1.29; 95%CI 1.27-1.30, p=<0.001) and diabetes (HR 1.13; 95%CI 1.04-1.22, p=<0.001) incidence when physical activity was not adjusted for. The increased risk for diabetes was unaffected when adjusting for physical activity (HR 1.11; 95%CI 1.01-1.19, p=<0.001). For CVD, the increased risk was attenuated but remained significant (HR 1.14; 95%CI 1.04-1.23, p=<0.001). Conclusions: Higher levels of total daily sitting time are associated with an increased risk of CVD and diabetes, independent of physical activity. Reductions in total daily sitting may thus be recommended in public health guidelines.
At population level, sedentary behaviours occupy the majority of adults’ waking hours. Based on accelerometry, adults may spend 50-60% of their day engaged in sedentary behaviours with an average daily sedentary time of 8.4 h.\textsuperscript{1} Sedentary behaviour includes a range of activities that involve sitting or lying down with minimal energy expenditure of ≤1.5 metabolic equivalents (METs) during waking time.\textsuperscript{2} Such activities include watching TV, sitting in a car, and office work. Sedentary behaviour is distinct from physical inactivity, which refers to insufficient levels of moderate-to-vigorous physical activity (MVPA). There have been a number of systematic reviews and meta-analyses that have explored the association of sedentary behaviour with cardiovascular disease (CVD) and Type 2 diabetes. One meta-analysis reported that TV viewing was associated with an increased risk of CVD and Type 2 diabetes.\textsuperscript{3} However, TV viewing time is a poor indicator of total sedentary time and may thus misclassify the true effect of this exposure on CVD and diabetes risk.\textsuperscript{4} Another meta-analysis reported that individuals who engaged in the highest amount of sedentary time had an increased risk of diabetes (112%) and cardiovascular events (147%) compared with those who engaged in the lowest amount of sedentary time.\textsuperscript{4} However, the meta-analysis conducted by Wilmot, et al.\textsuperscript{4} included both cross-sectional and prospective studies that varied considerable with regards to sedentary behaviour exposure (e.g. TV viewing, leisure-time sedentary behaviour and total sitting), which were combined in the same analysis. It was thus not possible to make conclusions regarding the prospective associations of total daily sitting time with CVD and diabetes, which could be important for public health guidelines.

The World Health Organization physical activity guidelines recommend that adults accumulate ≥150 min/week of moderate-intensity physical activity or ≥75 min/week of vigorous-intensity physical activity.\textsuperscript{5} However, there is no recommendation with respect to
sitting time and it remains unclear if increasing physical activity alone is sufficient for health or whether reductions in daily sitting are also required. Ekelund, et al. reported in a meta-analysis of more than 1 million adults that engaging in high levels (60-75 min/day) of moderate-intensity physical activity attenuated the increased mortality risk associated with high total daily sitting time. However, this level of daily physical activity may not be achievable for large amounts of the population and guidelines may thus need to recommend both increases in physical activity and reductions in sitting time. The meta-analysis by Wilmot, et al. demonstrated that the increased risk of CVD and diabetes with high amounts of sedentary behaviour (including measures of TV viewing, leisure-time sedentary behaviour and total daily sitting) remained, although was somewhat attenuated, after adjustment for physical activity. Two other meta-analyses showed that higher total daily sitting and higher sedentary time (including studies with total daily sitting and TV viewing as the exposure) were associated with increased incidence of CVD and Type 2 diabetes. However, they did not report whether adjustment for physical activity affected these associations. Thus, whether physical activity attenuates any potential associations of higher amounts of total daily sitting time with CVD and diabetes has not been evaluated and is required to inform public health guidelines. The aim of this study was to quantitatively synthesise prospective evidence relating total daily sitting time to incident CVD and diabetes with and without adjustment for physical activity.

Evidence acquisition

This review was conducted following the PRISMA guidelines and the protocol was registered with PROSPERO (registration number CRD42017054222). Ethical approval for the protocol was obtained from the Institute for Sport and Physical Activity Research Ethics Committee at the University of Bedfordshire (2018ISPAR004).
Study selection

A systematic search was conducted to identify relevant studies within the following databases: PubMed, Web of Science, BASE, MEDLINE, Academic Search Elite and ScienceDirect. The search terms used were: (“sitting time” OR “sedentary behavior” OR “sedentary behaviour” OR “sedentary lifestyle”) AND (“cardiometabolic disease” OR “cardiovascular disease” OR “diabetes” or “heart disease” or “stroke” OR “myocardial infarction” OR “angina” OR “heart failure” OR “heart attack” OR “coronary disease”) AND (“risk” OR “Cox” OR “hazard” OR “survival analysis” OR “odds”). Titles and abstracts were reviewed independently by R. B. Champion and D. P. Bailey and the full text was obtained for articles that were potentially eligible for inclusion and reviewed by the same authors. The reference lists of included articles and the authors’ personal collections were then checked to identify any additional articles for potential inclusion and were screened using the process described above.

Eligibility criteria

Studies published in English between 1st January 1989 and 15th February 2019 were included if they met the following criteria: (i) males and females aged 18 and over, healthy and disease free at baseline; (ii) observational prospective/follow-up studies that included a measure of total daily sitting time as an exposure variable collected subjectively via self-report or objectively via inclinometers; (iii) reported associations of different levels of total daily sitting time with objectively determined or self-reported CVD and/or diabetes incidence; and (iv) had an outcome of CVD or diabetes.

Data extraction and synthesis
Data was extracted from identified articles independently by two reviewers (D. P. Bailey and S. M. Sayegh), which was compared for consistency. The reviewers settled any discrepancies via discussion. The data extracted included the following: author(s), study design, sample size, mean follow-up duration, CVD or diabetes outcome, number of outcome cases, total sitting time measure, HR, RR or OR estimates with 95% CIs, and confounding variables adjusted for in the analysis. The measurement of total daily sitting time varied between studies with respect to grouping participants into different sitting categories using either quantile splits or arbitrarily determined groups that were not consistent across studies. The CVD and diabetes outcomes associated with the highest amount of total daily sitting were thus compared with the lowest amount of total daily sitting time for the purpose of this review to overcome these discrepancies in reporting. Corresponding authors were contacted by email to clarify or retrieve missing data and responses were incorporated into the analysis.

**Study appraisal**

The methodological quality of the selected articles was independently assessed by D. P. Bailey and S. M. Sayegh. Disagreements were resolved with scores from a third reviewer (R. B. Champion). A checklist developed from MOOSE (meta-analysis of observational studies in epidemiology) and STROBE (strengthening the reporting of observational studies in epidemiology) was used to assess the methodological quality of the studies. The total score available was 9 points: 1 point for a prospective study design, 1 point for reported reliability and 1 point for reported validity if sitting time was self-reported, 2 points if sitting time was objectively measured, 1 point if two or more confounders were controlled for in the analysis, 1 point if the analysis controlled for physical activity, 1 point if an objective measure of the health outcome was used, and 1 point for an adequate description of the
population. A score of ≥7 was considered high quality, 4-6 moderate quality and ≤3 poor quality.

Analysis

The HR or RR, and 95% CIs comparing the highest level of total daily sitting with the lowest were extracted from each study. Risk ratios were considered to be equal to HRs in this study. Data were extracted from the most adjusted model without physical activity adjustment and the least adjusted model with adjustment for physical activity. Where sitting time was reported in h/week, this was divided by seven to provide sitting time in h/day. If a study did not present HR or RR, the RR was calculated from the raw data.

Heterogeneity was calculated using the $I^2$ statistic and interpreted based on Higgins, et al. where 25%, 50% and 75% represent low, moderate and high heterogeneity, respectively. Four fixed-effects meta-analyses were performed following Cochrane guidelines: one for CVD outcomes without adjustment for physical activity, one for CVD outcomes with adjustment for physical activity, one for diabetes outcomes without adjustment for physical activity, and one for diabetes outcomes with adjustment for physical activity. Natural logarithm HRs were pooled across studies and weighted based on the inverse of variance for each study. Fixed effects models were used as there was no evidence of high heterogeneity across studies. Data are reported as mean effect HR (95% CI) and statistical significance accepted as p<0.05.

Evidence synthesis

Article selection
The PRISMA flow diagram of the article selection process is shown in Figure 1. The literature search resulted in 4304 articles, which was reduced to 2690 after removing duplicates. Titles and abstracts were then screened and 2670 were excluded on the basis that they did not meet the eligibility criteria for this review. This resulted in retrieval of 20 articles for full-text screening. Of these 20 articles, 11 were excluded as they did not satisfy the inclusion criteria, resulting in a total of nine articles being included for analysis.

Study characteristics

The characteristics and main outcomes for each study can be seen in Supplementary Table 1. Data from 224,414 participants were included in the CVD meta-analysis with 4,575 incidences during follow-up and 223,871 participants were included for diabetes with 11,472 incidences during follow-up. Five studies had diabetes as an outcome,\textsuperscript{15-19} three studies had CVD as an outcome,\textsuperscript{20-23} and one study reported outcomes separately for myocardial infarction and coronary heart disease.\textsuperscript{24} Data for 10 outcomes (CVD n=5; diabetes n=5) from these nine studies was thus included in the meta-analysis. The cohorts included were from a range of countries including Norway, Denmark, Finland, USA, Australia, and Britain. The mean age of the samples in these studies ranged from 44 to 64 years. Six studies included males and females in their sample\textsuperscript{15,17-21,24} and three studies included females only.\textsuperscript{16,22,23} The mean follow-up period ranged from 2.7 to 13.0 years. All studies used a single item self-report measure of total daily sitting time (see Supplementary Table 2) and divided sitting time into categories for analysis. The cut-points for these categories were not consistent across studies with the threshold for being in the highest sitting group ranging from $\geq 7.1$ h to $\geq 16$ h/day and the threshold for being in the lowest sitting group ranging from $<4$ h to $<8$ h/day. One study did not report the threshold for being in the highest and lowest daily sitting categories and instead reported the mean total daily sitting for this categories, which were
8.4±1.8 h vs. 2.7±0.8 h/day, respectively. Physical activity was self-reported in all studies using a range of different questions and categorisation approaches (see Supplementary Table 2) to measure leisure-time physical activity, MET-min or MET-h per week or MVPA. All studies other than Borodulin, et al.21 reported data for risk associations of total daily sitting time with CVD and diabetes with and without adjustment for physical activity.

**Study quality**

The overall quality of the studies included in this review was moderate to high (see Table 1). All included studies reported a prospective association. All studies used a self-report measure of sitting time. Four studies reported the validity and reliability of the self-report tool used,16,17,21,24 one study reported the validity only,19 and four studies did not report the validity or reliability of the tool used.15,18,22,23 The quality of the studies varied from 4/9 to 7/9.

**Associations of total daily sitting time with cardiovascular disease and diabetes incidence**

Higher total daily sitting time was associated with a significantly increased risk of CVD when physical activity was not adjusted for (HR 1.29; 95% CI 1.27, 1.30, p=<0.001); this risk was attenuated but remained significant with adjustment for physical activity (HR 1.14; 1.04, 1.23, p=<0.001). There was a significantly increased risk of diabetes associated with higher total daily sitting time without adjustment for physical activity (HR 1.13; 1.04, 1.22, p=<0.001) and this association was not attenuated with adjustment for physical activity (HR 1.11; 1.01, 1.19, p=<0.001). The forest plot of the hazards for higher amounts of total daily sitting can be seen in Figure 2 (without adjustment for physical activity) and Figure 3 (adjusted for physical activity).
Publication bias and heterogeneity

Publication bias was not assessed for either CVD or diabetes as there was a small number of published studies for each of these outcomes. However, visual inspection of the forest plot (Figures 2 and 3) would suggest that publication bias was likely not present for CVD or diabetes as there was no consistent pattern in studies with regards to the size of effect reported for smaller or larger sample sizes. Heterogeneity was low for CVD outcomes with and without adjustment for physical activity ($I^2=4\%, p=0.37, Q=3.122$ and $I^2=14\%, p=0.33, Q=4.647$, respectively) and moderate for diabetes outcomes both with and without adjustment for physical activity ($I^2=38\%, p=0.16, Q=6.503$ and $I^2=53\%, p=0.07, Q=8.538$, respectively).

Conclusions

This meta-analysis of prospective studies incorporating 448,285 participants demonstrates an increased risk for incidence of CVD and diabetes in individuals who engage in higher levels of total daily sitting time. The increased risk of diabetes was not attenuated after adjustment for physical activity, whereas the increased risk of CVD was attenuated, but remained significant, after adjustment for physical activity. This suggests that the risk of CVD and diabetes outcomes associated with higher levels of sitting time are independent of physical activity levels.

The findings of the present study are in agreement with previous meta-analyses demonstrating increased risk of CVD and diabetes in individuals who engage in higher levels of sedentary time.\textsuperscript{4,8} However, pooled HRs for incident diabetes associated with the higher levels of sedentary time were greater in magnitude than the present study; HR=1.91\textsuperscript{8} and 2.47 (without adjustment for physical activity).\textsuperscript{4} For CVD incidence, Wilmot, et al.\textsuperscript{4} reported a greater effect than the present study (HR=2.47), although in the study by Biswas, et al.\textsuperscript{8}, the
effect was similar (HR=1.14). The disparity in effects could be due to the type of sedentary 
behaviour exposures included e.g. TV viewing, leisure-time sedentary behaviour and/or total 
daily sitting time. For instance, the association of high daily sitting with all-cause mortality 
was attenuated with high physical activity levels, whereas the association with TV viewing 
time was not in a previous meta-analysis\textsuperscript{6}. The domain of sitting may thus affect the 
associations with health outcomes observed meaning it is not appropriate to combine 
different sitting time exposures in the same analysis. The findings of this current study 
address these limitations by including only total daily sitting time as the sedentary behaviour 
exposure.

The increased risk of CVD and diabetes associated with higher amounts of total daily sitting 
in the present study remained after adjustment for physical activity. This has also been 
documented in a previous meta-analysis comparing the highest to lowest group of sedentary 
time (including a mix of sedentary behaviour exposures) for these health outcomes.\textsuperscript{4} Two 
other meta-analyses showed that incident CVD and Type 2 diabetes risk was significantly 
positively associated with higher levels of sedentary time when adjusting for physical 
activity.\textsuperscript{7,8} However, these studies did not present data for models without physical activity 
adjustment, thus, whether physical activity attenuated this risk was unknown.\textsuperscript{7,8} Ekelund, et 
al.\textsuperscript{6} reported in their meta-analysis that the mortality risk associated with high amounts of 
total daily sitting were attenuated in individuals who engaged in high amounts (60-75 
min/day) of moderate-intensity physical activity. It was not feasible to use an approach 
similar to Ekelund, et al.\textsuperscript{6} in the present study as the included articles did not report on 
associations of sitting time with CVD and diabetes for separate physical activity categories. 
Future research should thus address this gap to inform CVD and diabetes prevention 
guidelines.
The independent associations of total daily sitting time with CVD and diabetes may be explained by a number of potential biological mechanisms. A number of experimental studies have shown that prolonged sitting results in higher levels of lipids, glucose and insulin, and that regularly interrupting sitting or substituting sitting with light, moderate or high-intensity physical activity attenuates these responses. Prolonged sitting is theorised to negatively affect carbohydrate metabolism via changes in muscle glucose transporter (GLUT) protein content and activity. Interrupting sitting with regular short bouts of physical activity upregulates glucose uptake pathways and alters gene expression that modulates lipid and glucose metabolism. In animal models, prolonged periods of muscular inactivity leads to decreased lipoprotein lipase activity (essential in the regulation of lipid levels) via cellular pathways uniquely different to exercise responses, although this requires confirmation in humans. Prolonged sitting can also cause vascular dysfunction via changes in blood flow and shear stress within blood vessels, thus promoting inflammation and atherosclerosis. However, it is not clear whether these suggested mechanisms can be applied to the current findings as the analysis was unable to examine the pattern of sitting time.

The major strength of this study is the meta-analysis for associations of total daily sitting time with CVD and diabetes outcomes with and without adjustment for physical activity. Inclusion of large population-based prospective cohort studies is also a strength. However, the studies included were limited to the use of self-report questionnaires to measure exposure. This is problematic as self-report measures underestimate total daily sitting time, which may lead to underestimations of health outcome risks associated with sitting time. Furthermore, only four studies reported the reliability and validity of the questions used. How questions are phrased, the time period they consider and whether assessed via a single question or
multiple domains can all affect validity of total daily sitting measures. Thus, there is a need for studies to employ objective measures of sitting time to address these limitations. Furthermore, the cut-points used to categorise high and low levels of daily sitting varied across studies. Although this may affect the associations reported in the individual studies and in this meta-analysis, there was low heterogeneity across studies for all sub-group analyses suggesting that this may not have affected this study’s findings. Moreover, physical activity was self-reported in all studies and the physical activity outcomes (e.g. leisure-time physical activity, MVPA, MET-h per week) were not consistent across studies. This could have affected the observed associations of sitting time with CVD and diabetes when adjusting for physical activity. Measuring total daily sitting and physical activity using devices would help to overcome some of these limitations in future research. There is also a need for further research to examine the joint associations of total daily sitting and physical activity with CVD and diabetes incidence to better determine if higher levels of physical activity may attenuate the negative cardiometabolic health outcomes associated with higher total daily sitting. Other limitations included the small number of prospective studies reporting on the association of total daily sitting with CVD and diabetes incidence and the use of only studies published in English.

In conclusion, this study suggests that higher levels of total daily sitting time are associated with an increased risk of CVD and diabetes, even after adjustment for physical activity. The findings support a focus on reducing total daily sitting time in public health guidelines and supports the need for experimental studies investigating the effectiveness of reducing daily sitting on cardiometabolic health.

Acknowledgements
No sources of funding supported this study. D. P. Bailey and S. M. Sayegh conceived the study and designed the experiments. D. P. Bailey, D. J. Hewson, R. B. Champion and S. M. Sayegh performed the experiments and wrote the paper. No financial disclosures were reported by the authors of this paper.
